This study is the first to examine the effectiveness of the *Fun FRIENDS* programme, a school-based, universal preventive intervention for early childhood anxiety and promotion of resilience delivered by classroom teachers. Participants ($N = 488$) included children aged 4–7 years attending 1 of 14 Catholic Education schools in Brisbane, Australia. The schools were randomly allocated to one of three groups, the intervention, active comparison and waitlist control group. Parents completed standardized measures of anxiety and behavioural inhibition (BI), resilience, social and emotional functioning and behaviour difficulties in addition to parental stress and anxiety, at pre- and post- and 12-month follow-up. Teachers also completed a parallel measure of social and emotional strength at the three time points. Comparable results were obtained for the intervention and comparison groups; however, the intervention group (IG) achieved greater reductions in BI, child behavioural difficulties and improvements in social and emotional competence. In addition, significant improvements in parenting distress and parent–child interactions were found for the IG, with gains maintained at 12-month follow-up. Teacher reports revealed more significant improvement in social and emotional competence for the IG. Clinical implications of the findings are discussed, along with limitations and directions for future research.

Keywords: child; anxiety; prevention; early intervention; universal

Introduction

Anxiety disorders are among the most prevalent psychiatric disorders in children and adolescents (Costello, Mustillo, Erkanli, Keeler, & Angold, 2003; Hirshfeld-Becker, Micco, Mazursky, Bruett, & Henin, 2011; Kessler et al., 2005). The prevalence of anxiety disorders in a community sample of preschool-aged children (2–5 years) has been reported as 9.5% (Edwards, Rapee, Kennedy, & Spence, 2010; Egger & Angold, 2006), with up to 28.8% of children developing an anxiety disorder during their lifetime (Kessler et al., 2005; Merikangas et al., 2010). If untreated, anxiety has the potential to cause significant disruption to a child's developmental trajectory due to the chronic course and low rates of remission (McLoone, Hudson, & Rapee, 2006). Furthermore, childhood anxiety may fail to be recognized because many anxious children present as shy, cooperative or compliant within the school setting (Albano, Chorpita, & Barlow, 2003). However, young children (under the age of 8 years) presenting with anxiety symptomatology have only recently been included in the intervention studies (van der Sluis, van Der Bruggen, Breechman-Toussaint, Thissen, & Bögels, 2012). Regardless of

the limited research focus, results have been promising in terms of the potential benefits of cognitive behavioural therapy (CBT)-based interventions for young anxious children (Cartwright-Hatton et al., 2011; Hirshfeld-Becker, Masek, et al., 2008; Hirshfeld-Becker, Micco, et al., 2008; Kennedy, Rapee, & Edwards, 2009; Monga, Young, & Owens, 2009; Pahl, Barrett & Gullo, 2012; Pincus, Santucci, Ehrenreich, & Eyberg, 2008; Rapee, Kennedy, Ingram, Edwards, & Sweeney, 2005; van der Sluis et al., 2012; Waters, Ford, Wharton, & Cobham, 2009).

The majority of children with anxiety disorders do not receive appropriate intervention (Hirshfeld-Becker et al., 1997; Merikangas et al., 2010; Olfson, Gameroff, Marcus, & Waslick, 2003; Sawyer et al., 2000). Research indicates that around 80% of children and adolescents in need of mental health services fail to receive such intervention (Cobham, 2012; Essau, 2005). A number of barriers to accessing psychological intervention exist including cost, time, availability, commitment and location particularly for families living in rural areas (Barrett & Pahl, 2006; Jorm & Wright, 2007). Many children presenting with anxiety suffer for years before receiving help (Thompson, Hunt, & Issakidis, 2004), with the average delay between symptom onset and consultation with a mental health professional ranging from 6 to 14 years (Christiana et al., 2000; Kessler, Walters, & Forthofer, 1998). An additional concern is treatment non-response, which may be associated with multiple factors (Donovan & Spence, 2000; Ginsburg et al., 2011). Taken together, these findings have inspired a conceptual shift in the development and implementation of mental health intervention worldwide (Delaney & Staten, 2010), from traditional models of psychological intervention delivery to an increased focus on prevention as a way of improving both the immediate health of children and young people and contributing to longer-term resilience. Consequently there has been an increased emphasis on developing innovative prevention protocols for preschool-aged children (Bayer et al., 2011; Bienvenu & Ginsburg, 2007; Fox, Haplern, & Forsyth, 2008; Fox et al., 2012; Hirshfeld-Becker & Biederman, 2002). Such early preventive interventions have the potential to reduce rates of depression, with anxiety typically preceding co-morbid depressive disorders (Bienvenu & Ginsburg, 2007; Flannery-Schroeder & Kendall, 2000), and may be most powerful when targeted at high-risk life transitions, such as entry to primary school or other significant transition points (Hirshfeld-Becker, Masek, et al., 2008), affording young children and their parents the opportunity to learn positive coping and emotional regulation skills. Given many of the barriers associated with accessing psychological intervention and the high drop-out rates, there is an increased need for cost-effective and accessible intervention delivered in a universal context such as the school environment.

CBT parent-based intervention

A review of the literature identified several studies addressing early prevention and intervention with this population, with many of these focused on the parent as the target of the intervention. One of the earliest studies incorporating a preventive intervention with an experimental design ($N = 45$) (LaFreniere & Capuano, 1997) assessed the effectiveness of a 20-session (6 months) integrated home-based prevention programme for anxious/withdrawn preschoolers. At post-intervention, significant immediate improvements in terms of teacher-rated social competence were identified for children in the intervention group (IG), with total levels of parental stress also achieving a significant decline over the 6-month intervention. Similarly, a pilot study examining the effectiveness of a selective prevention-based parent programme for anxiety and behavioural inhibition (BI) ($N = 7$)

(Rapee & Jacobs, 2002), which aimed to minimize cost through minimal therapist input and long-term educational value resulted in marked reductions in BI and anxiety diagnoses in children to 12-month follow-up.

In an extension to this study, Rapee et al. (2005) conducted a larger scale selective prevention study examining the effects of a universal CBT-based prevention programme for parents ($N = 146$, aged 36–62 months). The intervention was designed to be brief to provide maximum potential for public health implementation and targeted an identified risk factor for anxiety, an inhibited/withdrawn temperament and included six 90-min sessions. Children of parents in the educational parent group demonstrated a significantly greater decrease in anxiety diagnoses at 12-month follow-up, relative to the monitoring control condition.

The effectiveness of a parent-based early intervention programme facilitated in a group format ($N = 71$) (Kennedy et al., 2009) demonstrated a significant reduction in the frequency and severity of anxiety disorders and inhibition for children in the IG, relative to children on the waitlist with further improvement at 6-month follow-up. The findings provide further support for the benefits of early parent-based interventions to alter the developmental trajectory of anxiety in a high-risk group of young children.

The *REACH for RESILIENCE* ($N = 734$, aged 3–6 years), CBT-based intervention, developed exclusively for parents was trialed in 25 preschools over a 3-month time period using a controlled-trial design (Dadds & Roth, 2008). Results demonstrated decreases in teacher-reported internalizing and externalizing difficulties and a higher percentage of the IG moved from at-risk to low-risk status after the intervention. This study represents one of a very few universal trials with this population.

More recently, Rapee, Kennedy, Ingram, Edwards, and Sweeney (2010) conducted a randomized controlled trial of a brief parent-based intervention programme, designed to prevent anxiety in young children ($N = 146$). Children of parents that participated in the intervention were found to have a reduced risk of suffering from symptoms of anxiety at middle childhood (3-year follow-up). This study is significant in that it represents the first to demonstrate lasting changes in children's symptoms of anxiety, following a brief intervention in early childhood. This simple low-cost intervention may potentially alter the trajectory of anxiety and related disorders in young inhibited children and provides promise for the effectiveness of parent-based intervention for the prevention of early child anxiety.

A very recent study piloted the *Confident Kids programme* (van der Sluis et al., 2012), a CBT-based parent intervention developed for parents of children aged 4–7 years ($N = 26$). The intervention was delivered in four 2-h group parent sessions across a 4-week period, with parent's taking the role of 'therapist coaches' for their children. Comparable results to previous studies were obtained, with significant decreases in child anxiety and BI as reported by both parents and teachers (van der Sluis et al., 2012). This study provides further support of the value of incorporating a parental component to early intervention with young children.

CBT child- and parent-based interventions

A number of studies have examined the efficacy of early intervention for childhood anxiety, which include both child and parental components. For example, the efficacy of a CBT-based intervention for anxiety, the 'Being Brave' ($N = 64$) programme (Hirshfeld-Becker, Masek, et al., 2008; Hirshfeld-Becker et al., 2010). This programme is a developmentally appropriate manualized CBT-based intervention programme for children

and their parents, targeting identified risk factors for anxiety. Significant reductions in anxiety disorder diagnoses were obtained with outcomes maintained at 2-year follow-up. A similar intervention protocol for early childhood anxiety, *Taming 'Sneaky Fears'* ($N = 32$), based on a CBT framework (Monga, Young, & Owens, 2009) obtained comparable results, with significant reductions in anxiety disorder diagnoses and clinician-rated improvement in functioning. These findings are comparable with the results obtained following CBT protocols for older children (Barrett, Rapee, Dadds, & Ryan, 1996; Kendall, 1994; Kendall & Southam-Gerow, 1996) and provide promising preliminary data for the adaptation of a CBT-based parent and child protocol for early childhood and enhancing positive coping skills.

Waters et al. (2009) conducted a trial assessing the efficacy of a group-based cognitive behavioural intervention for young anxious children aged 4–8 years ($N = 80$). A parents-only CBT group intervention 'Take ACTION' was directly compared with the same intervention delivered to both children and parents, relative to a waitlist control condition. No significant differences between the two active conditions on other outcome measures were found. The study represents a valuable contribution to the literature, providing support for the exclusive delivery of a CBT intervention to parents of young anxious children as a viable intervention approach.

The first-ever universal school-based efficacy trial of the *Fun FRIENDS* programme (Barrett, 2007a, 2007b) was recently conducted for young children ($N = 263$) (Pahl & Barrett, 2010). This study represents one of very few universal trials, which focus on young anxious children, in addition to a parental component to the intervention. *Fun FRIENDS* is a developmentally appropriate, play-based CBT intervention and prevention programme for anxiety and social and emotional skill development, developed as a downward extension of the *FRIENDS for Life* programme (Barrett, 2004, 2005). Immediately post-intervention no significant differences were obtained; however, at 12-month follow-up, improvements were found on anxiety, BI and social-emotional competence for children in the IG. The results from this study provide support for the use of universal intervention programmes for young children implemented within the school context.

The most recent preventive intervention for anxious preschoolers and their parents involved a trial of the new *Strengthening Early Emotional Development* (SEED) programme (Fox et al., 2012) to promote social and emotional and behavioural competencies ($N = 16$, aged 3–5 years). SEED incorporates content from other evidence-based group programmes including the *Preschool PATHS* and the *Cool Kids* programme (Domitrovich, Cortes, & Greenberg, 2007; Rapee et al., 2006). The intervention produced improvements in child emotional knowledge and social reasoning skills in addition to reductions in parental anxiety and development of more positive parental attitudes towards their children, providing further support for the potential of preventive programmes for early childhood anxiety.

The above literature review indicates a number of areas of concern. First, anxiety disorders are among the most prevalent psychiatric disorders in young children (Edwards, Rapee, Kennedy, & Spence, 2010; Egger & Angold, 2006) and have the potential to cause significant developmental disruption (McLoone, Hudson, & Rapee, 2006); therefore, enhancing our understanding of risk and protective factors is critical. Second, the prevention of early childhood anxiety represents a significantly neglected area of research, with limited attention to the effectiveness of child-based early intervention and prevention programmes. Third, child-focused early interventions, which include a parental component, have produced promising outcomes for the prevention and treatment of

early child anxiety, and replication of these findings is required. Fourth, there is a clear need for cost-effective universal preventive interventions for young children.

Universal interventions where the population is the target of intervention (Mrazek & Haggerty, 1994) are receiving increasing support as viable and cost-effective approaches to early intervention for anxiety (Lowry-Webster, Barrett, & Dadds, 2001; Pahl & Barrett, 2010; Stallard et al., 2007). Schools represent an optimal context for prevention and early intervention efforts. The focus on the collective rather than individual level avoids labelling children and normalizes the promotion of positive social and emotional skills. This practice also increases maintenance of these skills due to the sustained daily contact with children, peer support and inclusion of social and emotional skill development as part of standard curriculum. Furthermore, this approach may neutralize many pragmatic and perceptual barriers to accessing community-based mental health services (Kendall, Settapani, & Cummings, 2012) and represents an ideal context to practice and perfect skill acquisition (Barrett & Pahl, 2006). Although there is a need for early intervention models, the effectiveness of such intervention protocols for younger children remains largely unknown (Egger & Angold, 2006; Eley et al., 2003; Spence, Rapee, McDonald, & Ingram, 2001; Sterba, Egger, & Angold, 2007), which highlights a need for a prevention programme with established effectiveness in this population.

The primary objective of this study was to extend Pahl and Barrett's (2010) pilot study and evaluate the effectiveness of the *Fun FRIENDS* intervention, delivered as a universal curriculum-based programme to reduce anxiety and BI and enhance social and emotional competence in young children. The study aimed to compare the outcome of the *Fun FRIENDS* IG) with the *You Can Do It* Active Comparison (CG) and waitlist control groups (WLGs) at pre-, post- and 12-month follow-up. It was hypothesized that the IG would be significantly more effective than the CG and that both interventions would be more effective than the waitlist. More specifically, it was hypothesized that child anxiety symptoms would decrease from pre- to post-intervention and continue to improve at follow-up for the IG. Furthermore, it was predicted that positive coping skills (approach behaviours, help seeking) and emotional regulation skills (self-soothing, anxiety management) would increase and maladaptive coping (avoidance behaviour and reassurance seeking) would decrease from pre- to post-intervention, for the IG with results maintained at a 12-month follow-up.

The second objective of the study was to explore whether it was possible to have a positive impact on levels of parental (mother and father) anxiety and distress. It was expected that maternal and paternal anxiety and distress in the IG would decrease as rates of anxiety decreased in the child. Thus, the inclusion of parents in the intervention may be critical in terms of educating parents and enhancing positive coping skills for themselves and their children.

Method

Recruitment

The schools were recruited via email correspondence sent by Brisbane Catholic Education Administration, Australia, inviting all 104 Catholic Education preschools and primary schools in the greater metropolitan area of Brisbane to participate in the research project. Sixteen schools that volunteered to participate following the initial email were contacted, and an information meeting outlining the project was held for principals and teachers for each of the 16 schools; 14 of the 16 schools that demonstrated initial interest agreed to participate in the study. The majority of the children attending these schools

(and characteristic of the general population of Brisbane) were White and working to middle class. Detailed information about ethnicity was not obtained.

Once the informed consent had been obtained from each of the principals, the participating schools were matched on socio-economic status and then the schools were randomly assigned to the IG, active CG or WLG. Following random assignment, letters were sent to the families in each school inviting parents to attend an information evening discussing the rationale for the research project and the details of what would be required of each family should they consent to participate.

Participants

The final sample consisted of 488 children (271 females, 217 males) between the ages of 4 and 7 years (mean age = 5.42 years, SD = 0.67) across 14 schools. Random assignment of the schools to the three conditions resulted in the final sample of 159 children (95 females, 64 males) in the IG, 196 children (101 females, 95 males) in the CG and 133 children (75 females, 58 males) in the WLG. In total, 440 fathers and 484 mothers completed the battery of questionnaires. Approximately 3.3% of the sample reported an annual family income (Australian dollars) under \$30,000, 13.3% between \$30,000 and \$60,000 and 76.5% of the sample reported an income above \$60,000. The schools ranged in terms of enrolment number from 249 to 641 students and socio-economic status of the schools ranged from 1033 to 1200 based on the Index of Community Socio-Educational Advantage (mean = 1000, SD = 100). The number of prep and pre-prep classes varied across the schools from 1 to 4 classes participating in the research; 31 teachers participated in the study.

Measures

Parents and teachers of children who consented to be involved in the research completed a battery of questionnaires at three different points in time (pre-intervention, post-intervention and 12-month follow-up). These measures are detailed below.

Parent-completed measures for child

Preschool Anxiety Scale. The *Preschool Anxiety Scale* (PAS; Spence et al., 2001), adapted from the Spence Children's Anxiety Scale, is a 34-item parent report assessment designed to assess childhood anxiety symptoms as defined by the *Diagnostic and statistical manual*, fourth edition (DSM-IV, APA, 2000). The PAS provides a total score of anxiety (minimum score 0, to a maximum score of 112), in addition to five subscale scores: separation anxiety, physical injury fears, social phobia, obsessive-compulsive disorder and generalized anxiety disorder. The PAS has adequate psychometric properties and good construct validity with the child behaviour checklist (Achenbach, 1991, 1992; Achenbach & Rescorla, 2000), correlations ranging from 0.59 to 0.68. Both parents completed the PAS conjointly in this study.

Behavioural Inhibition Questionnaire. The *Behavioural Inhibition Questionnaire* (BIQ; Bishop, Spence, & McDonald, 2003) is a 30-item parent report questionnaire assessing the frequency of behaviours associated with BI across a 7-point Likert scale. The measure provides a total BI score, in addition to six specific scores characteristic of BI: peer situations, physical challenge, separation/preschool, performance situations, unfamiliar

adults and general novel situations. The BIQ has demonstrated good psychometric properties, with high internal consistency (0.87 for mother report, 0.85 for father report) and strong convergent validity (0.87 for mother, 0.86 for father) against the inhibition scale of the 'Temperament assessment battery for children – revised' (Martin, 1994), and good internal consistency for all informants. Parents were invited to complete this measure conjointly.

Behavioural and Emotional Rating Scale, second edition. The *Behavioural and Emotional Rating Scale* (BERS-2; Epstein & Sharma, 1997) is a 52-item parent report measure, designed to assess five factors related to children's emotional and behaviour strengths: interpersonal strengths, family involvement, intrapersonal strength, school functioning and affective strength. The BERS-2 has demonstrated excellent inter-rater reliability ($r > 0.83$) and moderate to excellent test–retest reliability ranging from 0.53 to 0.99 (Epstein et al., 1999). This measure was used to assess social–emotional competence, parents were invited to complete this conjointly.

Strengths and Difficulties Questionnaire. The *Strengths and Difficulties Questionnaire* (SDQ; Goodman, 1997) is a 25-item measure designed to assess psychological adjustment in children aged 3–16 years. The items are divided between following five scales: emotional difficulties, conduct problems, hyperactivity and inattention, peer difficulties, and pro-social behaviour. Participants are required to indicate either 'not true' (0), 'somewhat true' (1) or 'certainly true' (2) for each of the statements, with higher scores indicative of more significant problems for each subscale, excluding pro-social behaviour where higher scores indicate positive adjustment. The SDQ has sound psychometric properties for all subscales (Vostanis et al., 2006), internal consistency (mean Cronbach's α : 0.73), cross-informant correlation (mean: 0.34), or retest stability after 4–6 months (mean: 0.62). (Goodman, 2001; Goodman & Scott, 1999). Assessment of the psychometric properties of the SDQ based on an Australian sample generated evidence moderate to strong internal reliability across all SDQ subscales (Hawes & Dadds, 2004). Adequate validity was also achieved in terms of the relationship of the SDQ subscales to one another. In addition correlations between the subscales, teacher ratings and diagnostic interviews demonstrated sound external validity (Hawes & Dadds, 2004). Parents were invited to complete this measure conjointly.

Devereux Early Childhood Assessment Clinical Form. The *Devereux Early Childhood Assessment Clinical Form* (DECA-C; LeBuffe & Naglieri, 1999) is a standardized norm-referenced behaviour rating scale that evaluates behaviour related to social and emotional resilience and concerns in preschool-aged children aged 2–5 years. The DECA evaluates the frequency of positive behaviours (strengths) and negative behaviours (concerns). The positive behaviours related to resilience include three Protective Factors Scales: initiative (11 items), self-control (8 items) and attachment (8 items). The Total Protective Factors Scale is a composite of the three scales and provides an overall indication of the strength of the child's protective factors. The behaviours related to social and emotional problems comprise four Behavioural Concern Scales; attention problems (7 items), aggression (7 items), emotional control problems (8 items) and withdrawn/depressed (9 items). A Total Behavioural Concerns Scale is a composite of the four-behavioural concern scales, and it provides an overall index of the magnitude and severity of the child's

behavioural problems. Studies indicate that the DECA-C is a reliable instrument for assessing social and emotional competence and behaviour in preschool-aged children (Buhs, 2003; Chittooran, 2003; Reddy, 2007). Internal reliability alpha coefficients for parents range from a low of 0.66 on withdrawal/depression to 0.78 on emotional control problems, with a median of 0.76. The development and standardization of the DECA, including all original psychometric studies, are described in detail in the DECA technical manual (LeBuffe & Naglieri, 1999). The DECA was normed on a representative American sample of 2000 children across 28 states. Half of the children in the sample were rated by a parent or other family caregiver and half by a preschool teacher. It is important to note that while the measure was normed on a sample of children aged 2–5 years, in the current trial, the DECA was administered to all children in the sample with ages ranging from 4 to 7 years. Parents were invited to complete this measure conjointly.

Parent-completed measures for self

Depression, Anxiety and Stress Scale. The *Depression, Anxiety and Stress Scale* (DASS-21; Lovibond & Lovibond, 1995) is a 21-item self-report assessment measure. This measure provides an assessment of parental anxiety, depression and stress. The measure has demonstrated excellent psychometric properties with good reliability, with Cronbach's α ranging from 0.73 to 0.82 for the anxiety subscale and 0.82 for depression (Clara, Cox, & Enns, 2001; Henry & Crawford, 2005; Lovibond & Lovibond, 1995). Studies have reported good estimates of internal consistency reliability for scale scores (range = 0.82–0.97) in both clinical and non-clinical samples (e.g. Henry & Crawford, 2005; Lovibond & Lovibond, 1995). The measure has also been found to correlate strongly with other widely used measures of depression and anxiety (Augustine et al., 2012; Sukantarat, Williamson, & Brett, 2007). Mothers and fathers were invited to complete this measure independently from one another.

Hospital Anxiety and Depression Scale. The *Hospital Anxiety and Depression Scale* (HADS; Zigmond & Snaith, 1983) is a self-assessment instrument for detecting clinically significant depression and anxiety in patients attending outpatient medical clinics and for discriminating between anxiety and depression. It has been widely used as a screening instrument outside of the hospital setting and also for rating psychiatric patients. The HADS is a self-report, 14-item scale with seven items measuring anxiety (HADS-A) and seven measuring depression (HADS-D). Scores range from 0 to 21 for each scale; higher scores represent more distress. The time frame refers to mood during the previous week. The HADS appears to have psychometric properties, with correlations between the two subscales reported to vary from 0.40 to 0.74 (mean 0.56) (Bjelland, Dahl, Haug, & Neckelmann, 2002). Cronbach's α for HADS-A varied from 0.68 to 0.93 (mean 0.83) and for HADS-D from 0.67 to 0.90 (mean 0.82). The sensitivity and specificity for both HADS-A and HADS-D (0.80) were reported to be consistent with the *General Health Questionnaire* (Goldberg, 1978). Correlations between the HADS and other commonly used questionnaires designed to assess anxiety and depression were reported to be within the range of 0.49 to 0.83. (Bjelland et al., 2002). Mothers and fathers were invited to complete this measure independently.

Parenting Stress Index, Short Form. The *Parenting Stress Index, Short Form* (PSI-SF; Abidin, 1994) is a 36-item parent report measure, which provides an overall measure of

stress within the parent child relationship and includes three subscales: parental distress, parent-child dysfunctional interaction and difficult child. The PSI-SF is designed for the early identification of parenting and family characteristics that fail to promote normal development and functioning in children, children with behavioural and emotional problems and parents who are at risk for dysfunctional parenting. Studies of test-retest reliability ($r = 0.84$) and internal consistency ($\alpha = 0.91$) demonstrate high to excellent reliability (Abidin, 1994). The total score on the PSI-SF was used as a measure of parenting stress. Mothers and fathers were invited to complete this measure independently.

Measure completed by teachers

The *DECA-C Teacher Report* (LeBuffe & Naglieri, 1999) is identical to the parent report form. This is a standardized, norm-referenced behaviour rating scale that evaluates social and emotional resilience and concerns in preschool-aged children. The DECA evaluates the frequency of positive behaviours (strengths) and negative behaviours (concerns). For teachers, the alpha coefficients range from 0.80 on withdrawal/depression to 0.90 on attention problems, with a median of 0.88.

Procedure

Phase one: pre-assessment screening

All parents were sent an information sheet and pre-assessment questionnaire detailing the research project. Participants were informed that all responses would be confidential and would only be viewed by research staff and that they were free to withdraw at any time. In addition, it was made clear that the intervention would be delivered during class time and at no cost to parents. None of the schools involved in this research project had been directly involved with the *Fun FRIENDS* programme before this research project. Of the 14 schools that agreed to participate, none of the parents refused to allow their child to participate in the programme, and this is consistent with the pilot *Fun FRIENDS* study (Pahl & Barrett, 2010) and is likely because the programme was implemented as part of school curriculum.

Pre-intervention assessment was conducted within a 2-week time period with questionnaires sent to teachers and parents through school administration, with the completed questionnaires returned to classroom teachers. Teachers completed the DECA for each child in their class participating in the research. The option to complete the questionnaires individually with the researcher was offered to parents to ensure all participants comprehended the questions regardless of academic or English language ability.

Post-intervention assessment was conducted within two weeks of completion of the programme and approximately 24 weeks following pre-assessment screening. At 12-month follow-up the same procedure was adhered to, with schools sending the questionnaires to parents and collected by the classroom teachers within a 2-week time limit.

Intervention

Intervention protocol – Fun FRIENDS

The intervention programme used was the *Fun FRIENDS* programme. *Fun FRIENDS* is a developmentally appropriate downward extension of the *FRIENDS for Life* programme

created for the prevention of anxiety and promotion of social and emotional skills and resilience in early childhood (Barrett, 2007a). The programme name *Fun FRIENDS* is an acronym for the strategies taught within the programme, with each letter corresponding to a specific skill. See Table 1, for a description of session content. The primary components of the programme include relaxation, cognitive restructuring, attention training and graded exposure to anxiety provoking situations and problem solving, which are facilitated by peer and family support. The *Fun FRIENDS* programme actively involves parents, teachers and children to promote skill acquisition and reinforcement of skills across contexts.

The intervention commenced approximately 2 weeks following pre-intervention assessment. Teachers were advised that the programmes were to be delivered across two

Table 1. Outline of the *Fun FRIENDS* session content.

Session	Content of session – major learning objectives
Session 1	<ul style="list-style-type: none"> • Developing a sense of identity, introduction to the group, name games. • Introduction of the concept of ‘being brave’, social skills promotion. • Acceptance of differences.
Session 2	<p>F: Feelings</p> <ul style="list-style-type: none"> • Affective education and identification of various emotions, including recognition of physiological arousal associated with emotions.
Session 3	<p>F: Feelings (continued)</p> <ul style="list-style-type: none"> • How to cope with feelings, thumbs-up ideas (helpful coping behaviours) and thumbs-down ideas (unhelpful coping behaviours). • Building on understanding the link between feelings and behaviour. • Strategies to help others when they experience feelings, assists with development of empathy.
Session 4	<p>R: Remember to relax</p> <ul style="list-style-type: none"> • Identification of physiological arousal (‘body clues’) related to anxiety. • Relaxation strategies are taught including, diaphragmatic breathings (‘milkshake breathing’), progressive muscle relaxation and visualization.
Session 5	<p>I: I can try my best!</p> <ul style="list-style-type: none"> • Introduction to the cognitive components of the program. • Children are taught to become aware of and pay attention to their inner thoughts or self-talk. • Self-talk is referred to in terms of ‘red’ unhelpful thoughts and ‘Green’ – helpful thoughts, using the traffic light analogy.
Session 6	<p>I: I can try my best! (continued)</p> <ul style="list-style-type: none"> • Introduction to challenging unhelpful ‘red’ thoughts and come up with alternative helpful green thoughts. • Application of green thoughts to help us achieve our goals.
Session 7	<p>E: Encourage</p> <ul style="list-style-type: none"> • Try new things by breaking tasks down into small steps and using green thinking to help achieve goals.
Session 8	<p>N: Nurture</p> <ul style="list-style-type: none"> • Introduce idea of role models and support teams, those people who help us to achieve our goals.
Session 9	<p>D: Don’t forget to be brave</p> <ul style="list-style-type: none"> • Support teams continued. • Planning ahead for difficult situations.
Session 10	<p>S: Stay smiling</p> <ul style="list-style-type: none"> • Children dress up as their favourite brave person and celebrate their success in completing the program. Review strategies and skills.
Two booster sessions	Review of <i>Fun FRIENDS</i> strategies and preparing for future challenges.

school terms with a recommended delivery schedule of one session per week. Furthermore, the teachers were instructed that the programme was to be delivered in chronological order; however, there was significant opportunity for creativity within each session. Teachers were provided with a leader's manual outlining the content and process for each of the 10 sessions (Barrett, 2007a), and each child was provided with a *Family Learning Adventure* workbook, which provides step-by-step instruction for home implementation of the session skills (Barrett, 2007b).

Teacher training. Before commencement of the programme all classroom teachers across the four schools allocated to the IG attended a 1-day intensive training workshop, which provided psycho-education about childhood anxiety, the theoretical rationale of *Fun FRIENDS* and instruction in delivery and facilitation of the programme. Content also addressed ethical issues associated with running groups with children and group process skills. The *Fun FRIENDS* Group Leader Manual (Barrett, 2007a), training aids, handouts, exercises, discussion questions, videos and overheads were standardized across training workshops via a training manual and resource kit (Barrett, 2007a). The lead researcher, a registered clinical psychologist, was responsible for conducting the training of all teachers allocated to the *Fun FRIENDS* programme in addition to facilitating parent talks for all of the participating schools. Regular contact was initiated by the lead researcher with all teachers from the participating schools to provide support and answer questions relating to the implementation of the programmes or address any questions arising. In addition, the *You Can Do It* team was also available for consultation through the lead researcher to address questions arising from the implementation of this programme. Regular consultation and communication with parents across all of the 14 schools was also maintained through updates in school newsletters. Parents were also provided with the contact details of the researchers if they wish to discuss any concerns or provide feedback. To assess the integrity of the intervention protocol, the teachers within the *Fun FRIENDS* IG were required to complete a weekly checklist indicating compliance with the manual session content.

Parent sessions. Parents were encouraged to attend two parent sessions across the course of programme implementation and coincided Sessions 4 and 7. Parent sessions were conducted during the evening to increase the possibility that both parents may be able to attend. Session content included educating parents about child anxiety, social and emotional competence and resilience and outlined each of the component skills of the *Fun FRIENDS* programme. Parents were encouraged to practice the skills and strategies in the home environment to ensure generalization across contexts.

Intervention protocol – the You Can Do It CG

The *You Can Do It* CBT-based social and emotional skills were included as an active control condition. This programme is endorsed as an effective school-based programme, designed to be delivered at a universal level by teachers in the classroom setting to promote confidence and social and emotional strength (Ashdown & Bernard, 2012; Bernard, 2006). A recent study, similar in design to the current trial, examined the effect of the *You Can Do It* programme on the social and emotional development and academic achievement of preparatory and grade 1 students attending a Catholic school in Melbourne, Australia ($N = 99$) (Ashdown & Bernard, 2012; Bernard & Walton, 2011). The programme was delivered over 10 weeks by classroom teachers, with results indicating a statistically

significant improvement in social and emotional competence and well-being in children and a reduction in problem behaviours as rated by teachers.

Unlike the *Fun FRIENDS* programme, *You Can Do It* does not involve any specific training for facilitators in terms of the implementation of the programme. Teachers received the programme material and manual and were required to administer the programme as per the implementation directions.

The main objective of the *You Can Do It* programme is the development of young people's social and emotional capabilities, including confidence, persistence, organization, getting along and resilience. Central to the development of these 5 foundations is instilling in young people 12 habits of the mind that support and foster the 5 foundations, including Accepting Myself, Taking Risks, Being Independent, I Can Do It, Giving Effort, Working Tough, Setting Goals, Planning My Time, Being Tolerant of Others, Thinking First, Playing by the Rules and Social Responsibility (includes the values of Caring, Doing Your Best, Freedom, Honesty, Integrity, Respect, Responsibility, Understanding, Tolerance and Inclusion) (Bernard, 2001).

Parent training. The same initial parent information evening that was offered to parents in the IG was also offered to the CG. An additional parent session was conducted by *You Can Do It* programme educators half way through the programme to provide parents with further information about how to reinforce the skills at home. The parent evenings at each of the schools was facilitated by the Director of the *You Can Do It* programme.

Programme implementation. Following consent and completion of the same battery of questionnaires as the IG, the schools were provided with the *You Can Do It* programme and resources. The teachers were responsible for implementing the programme as per the guidelines for teachers set out in the manual. As per the IG, the comparison *You Can Do It* programme was implemented once per week for approximately 1 h across school's two terms, facilitated by classroom teachers. A registered psychologist was available during the period of implementation to provide support for the teachers and respond to questions. Teachers were provided with the programme manual and all required props and puppets.

Waitlist group

The five schools allocated to the monitoring CG received the same initial parent information evening. The identical process of completing questionnaires was followed as for the IG and CG, with questionnaires completed at pre-, post- and 12-month follow-up. The schools continued with standard curriculum as normal for the 12-month wait period, with clinical psychologists available for consultation during this period of time. Following the 12-month wait, all of the schools were offered the *Fun FRIENDS* programme.

Results

Preliminary analysis

Preliminary analysis revealed large amounts of missing data for each of the father response measures (ranging from 25% for the defensive responding scale to 16% for the DASS-21). The PSI-SF was not completed by 10% of mothers at follow-up and 8% of mothers at post-test. All remaining variables had <6% missing data.

In all, 200 of the 488 participants were missing on at least one observation. There were 15 cases that were missing on more than 30% of their data, and these data were removed to prevent potential bias arising from these non-responders. For the remaining participants, data were clustered according to the pattern of responding using the VIM package in R (R Development Core Team, 2007). Only one clear pattern of missing data was observed, with 6.3% of respondents missing all father response data. The remaining participants showed no tendency to respond in any given pattern, suggesting that the data appear to be effectively missing at random across the data set. Due to the large amounts of missing data on some variables, it was decided to analyze only complete data points, using linear mixed-effects models for the analysis of the overall effect of the intervention. Linear mixed-effects models include all observations, which are valid at each time point and are recommended as they reduce bias, which might otherwise be created in excluding those respondents with incomplete data (Cnaan, Laird, & Slassor, 1998). Although there may still be issues of generalizability of the findings, the analysis of complete data is less problematic for multivariate analyses than is imputation of data when data are extensively missing as these analyses make less assumptions about the nature of the missing data and therefore produce less biased estimates (Kalton & Kasprzyk, 1982).

An examination of the distributions of the continuous measures revealed significant skewness and significant outliers among a large number of clinical measures. For each variable that was significantly skewed an appropriate transform was identified from the ladder of powers (square root, log, inverse and inverse log), which transformed the variable to non-significantly skew (Tabachnick & Fidell, 2007). All of the parent BERS-2 measures were negatively skewed, as well as the following Parent report subscales on the DECA: attachment, initiative, protective factors and self-control. The parent report hyperactivity subscale on the SDQ was also negatively skewed. These variables were reflected before transformation and then re-reflected to retain their direction. Only the BIQ social novelty scale could not be transformed with this method, this variable was transformed using the best power transform using the Box–Cox procedure (Box & Cox, 1964). The optimal power for this variable was 0.72. Significant outliers were winsorized at three standard deviations to reduce their influence on analyses (Tabachnick & Fidell, 2007) (Tables 2 and 3).

Table 2. Demographics of the IG, comparison and waitlist groups.

Age in years	Mean (SD)	Intervention		
		Fun Friends	You can do it	Wait-list
Number of respondents	<i>N</i>	159	196	133

Exploratory factor analysis – parent data

An exploratory factor analysis was conducted on all measures using principal axis factoring with oblimin rotation. Examination of the scree plot (Figure 1) showed potentially five factors with eigenvalues > 1 and a discontinuity after the fifth factor. Examination of both the four- and five-factor solutions revealed an identical factor structure for the first four factors, whereas the fifth factor comprised only a single variable; the DECA Protective Factors Scale, which loaded more strongly on the second than on the fifth factor; therefore, the four-factor solution was preferred in the interest of interpretability.

An examination of the factor loadings (Table 4) for the oblique factor solution revealed a simple structure. Based on the interpretation of the factor loadings, the first factor was labelled behavioural and emotional functioning as it comprised only five items from the BERS-2 scale, the second was labelled behavioural difficulties (as it positively loaded behavioural problems from the SDQ (four items) and DECA (five items) and negatively loaded protective factors from both tests) the third was labelled inhibition because it comprised the PAS social anxiety scale, the BIQ social and situational novelty scales, and the BIQ physical challenges scale, and the fourth factor was labelled parenting stress as it comprised six items solely from the PSI. After standardization of the items, Cronbach's α s for the index items on each scale were 0.86 (factor 1), 0.88 (factor 2), 0.78 (factor 3) and 0.86 (factor 4). Intercorrelations between the factors are provided in Table 5.

Baseline differences

Preliminary one-way ANOVAs on each of the factors revealed that there was no significant difference in the baseline scores for factor 4; however, significant baseline differences were identified between the groups on factors 1 through 3 ($F(2,470) = 13.54$, $p < 0.001$ for factor 1, $F(2,466) = 3.31$, $p = 0.037$ for factor 2, $F(2,470) = 17.33$, $p < 0.001$). For factor 1 the waitlist group scored significantly higher than either of the two treatment groups ($p < 0.05$), but the treatment groups did not differ significantly. For factor 2 (behavioural difficulties), the waitlist group scored significantly higher than the *Fun FRIENDS* [Please note that 'Fun FRIENDS' and 'Fun-Friends' have been changed to '*Fun FRIENDS*' throughout the article for consistency. Please check and confirm.], but not the *You Can Do It* group ($p < 0.05$), whereas for factor 3, the waitlist group scored

significantly lower than both of the treatment groups and in addition, the *You Can Do It* group scored significantly higher than the *Fun FRIENDS* group ($p < 0.05$). To account for this, the follow-up analyses for the group differences were performed using ANCOVA controlling for baseline scores as recommended by Rausch, Maxwell, and Kelley (2003).

Intervention effects

A two-way linear mixed-effects model was conducted examining each of the factor scores at three time points (pre-test, post-test and at 12-month follow-up) for each of the three groups (*Fun FRIENDS*, *You Can Do It* and Waitlist). Models included time as a categorical repeated measures factor, group as a categorical between-subjects factor and participant identification and school as a random factor to account for the nested nature of the design. Models were compared using a variety of covariance structures as is recommended, including first-order autoregressive, compound symmetry and scaled identity, and model selection was based on the Akaike Information Criterion (AIC). For factors 2 and 3, the first-order autoregressive model provided the best fit, whereas for factors 1 and 4, the compound symmetry model provided the lower AIC.

Behavioural and emotional strength

Analysis revealed significant main effects of time for all factors (refer to Figure 2 for a summary of the Four Factor Scores at Pre, Post and 12 month follow up) [$F(2,939) = 453.84$, $p < 0.001$ for behavioural and emotional strength, $F(2,912.92) = 299.85$, $p < 0.001$ for behavioural difficulties, $F(2,971.14) = 289.99$, $p < 0.001$ for BI, and $F(2,897.89) = 55.32$, $p < 0.001$ for Parenting Stress). There were significant two-way interactions between time and group for factors 1–3 ($F(4,939.01) = 50.39$, $p < 0.001$ for BERS-2, $F(4,912.93) = 6.37$, $p < 0.001$ for behavioural difficulties, and $F(971.14) = 59.62$, $p < 0.001$ for inhibition].

For the three factors that exhibited a significant interaction, simple effects of time were examined for each of the three IGs. Analysis revealed that for behavioural and emotional

waitlist group ($p = 0.007$) at post-test and improved significantly more than both other groups at follow-up ($p < 0.001$). The *You Can Do It* group improved significantly more than the waitlist group at follow-up ($p < 0.001$) but not at post-test ($p = 0.061$).

Behavioural difficulties

All groups differed significantly from pre-test to post-test, in terms of behavioural difficulties and continued to improve from post-test to follow-up ($F(2,310) = 202.75, p < 0.001$ for *Fun FRIENDS*, $F(2,362) = 85.31, p < 0.001$ for *You Can Do It*, and $F(2,253) = 32.69, p < 0.001$ for the waitlist group). Controlling for baseline scores, both the *Fun FRIENDS* group and the *You Can Do It* group improved significantly more than the waitlist group at post-test ($p < 0.001$ and $p = 0.002$, respectively), whereas the *Fun FRIENDS* and *You Can Do It* groups did not differ ($p = 0.095$). At follow-up, neither group improved significantly more than the waitlist, controlling for baseline scores; however, the *Fun FRIENDS* group did improve significantly more than the *You Can Do It* group ($p = 0.021$).

Behavioural inhibition

In terms of BI, both the *Fun FRIENDS* and the CG improved significantly from pre-test to post-test and then continued to improve significantly from post-test to follow-up ($F(2,327.4) = 375.77, p < 0.001$ for *Fun FRIENDS*, and $F(2,384.69) = 106.84, p < 0.001$ for *You Can Do It*), while the waitlist group did not improve significantly from pre-test to post-test or from post-test to follow-up, but did have overall lower scores at follow-up than at pre-test ($F(2,260.68) = 3.23, p < 0.001$). Controlling for baseline scores, both the *Fun FRIENDS* and *You Can Do It* groups improved significantly more

than the waitlist group, and the *Fun FRIENDS* group improved significantly more than the *You Can Do It* group both at post-test and at follow-up (all $ps < 0.001$).

Comparison of the Fun FRIENDS intervention for high- versus low-anxious children

To establish whether the *Fun FRIENDS* intervention was significantly more effective for high-anxious children than for low-anxious, those children scoring in the top third on the PAS total score were compared with those scoring in the bottom third of the group. Two-way linear mixed-effects models were conducted comparing the high- and low-anxious children in terms of their intervention gains, and the interaction term was examined to determine whether a significant difference in improvement existed according to the baseline anxiety of the child.

Significant interactions were found for the behavioural and emotional strength factor [$F(2,184.19) = 5.16, p = 0.007$], the behavioural difficulties factor ($F(2,189.54) = 4.32, p = 0.015$) and the BI factor [$F(2,179.42) = 15.48, p < 0.001$]. Follow-up simple effects for the BERS-2 factor demonstrated that both high- and low-anxious children improved significantly from pre-test to post-test and from post-test to follow-up; however, this improvement was greater for the high-anxious children. The examination of Figure 3 shows that although the high-anxious children initially displayed lower scores than the low-anxious group, by the follow-up time point both groups had equivalent scores.

Follow-up simple effects of time for the Behavioural difficulties factor showed significant intervention effects for both the high-anxious group [$F(2,106.45) = 43.85, p < 0.001$] than for the low-anxious group [$F(2,74.2) = 44.4, p < 0.001$]. Both high- and low-anxious groups improved from pre-test to post-test, and both reverted to some extent at the follow-up, but were still significantly improved relative to baseline. The high-anxious group however experienced slightly more improvement (and reverted slightly more) than the low-anxious group (see Figure 4).

Figure 3. Levels of social and emotional competence at pre-, post- and follow-up for the *Fun FRIENDS* group.

Figure 4. Levels of behavioural difficulty at pre-, post- and follow-up for the *Fun FRIENDS* group.

Follow-up simple effects of time for the inhibition factor showed greater intervention effects for the high-anxious group [$F(2,224.15) = 194.26, p < 0.001$] than for the low-anxious group [$F(2,224.15) = 107.79, p < 0.001$]. Both high- and low-anxious groups improved from pre-test to post-test, but only the high-anxious group continued to improve from post-test to follow-up. For the inhibition measure, the high-anxious group did not reach the same performance level as the low-anxious group (Figure 5).

Figure 5. Levels of BI at pre-, post- and follow-up for the *Fun FRIENDS* group.

Teacher protective factors rating

A two-way linear mixed-effects model conducted on the teacher ratings of the DECA Protective Factors Scale. Analysis revealed a significant main effect of time, $F(2,904.54) = 32.68$, $p < 0.001$. Analysis also revealed a significant time \times group interaction, $F(4,904.55) = 8.699$, $p < 0.001$. Only the *Fun FRIENDS* group changed significantly over time, $F(2,284) = 35.69$, $p < 0.001$. The *Fun FRIENDS* group improved significantly from pre-test to post-test and maintained this level of function at follow-up (refer Figure 7). Controlling for baseline differences, the *Fun FRIENDS* group improved significantly more than either the *You Can Do It* group or waitlist group at both post-test and follow-up ($ps < 0.001$), whereas the *You Can Do It* and waitlist groups did not differ significantly refer Figure 6.

A supplementary analysis was then conducted comparing teacher and parent ratings of the DECA protective factors. The analysis revealed a significant large main effect of respondent, such that parents overall rated the Protective Factors Scale higher than did teachers $F(1,751.43) = 334.76$, $p < 0.001$, as well as a main effect of time, $F(2,745.78) = 433.93$, $p < 0.001$, and a significant two-way interaction between respondent and time $F(2,745.78) = 192.14$, $p < 0.001$. There were significant simple effects of time for both parents, $F(2,309.13) = 916.63$, $p < 0.001$, and teachers, $F(2,282.82) = 38.76$, $p < 0.001$. For both kinds of respondents, the post-test scores differed significantly to pre-test scores, and follow-up scores did not differ significantly to scores at post-test. Parents however showed significantly larger intervention effects than did teachers (refer to Figure 6 for a comparison of Parent and Teacher protective factors across the three groups. Refer Figure 7).

Comparison of mother and father distress ratings

A two-way linear mixed-effects model comparing mother and father ratings of parental distress revealed a very large main effect of respondent, $F(1,713.661) = 4173.673$, $p < 0.001$, such that fathers rated their distress a great deal higher overall than did mothers. There was also a significant main effect of time, $F(2,698.55) = 24.92$, $p < 0.001$, such that scores improved significantly from pre-test to post-test for both groups, but did not change from post-test to follow-up. There was no significant interaction between the factors, $F(2,695.87) = 2.13$, $p = 0.119$ (Figure 8).

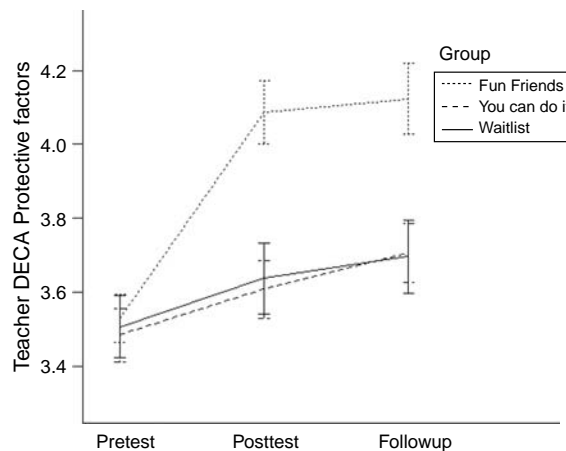

Figure 6. Teacher protective factors at pre-, post- and follow-up for the *Fun FRIENDS* group.

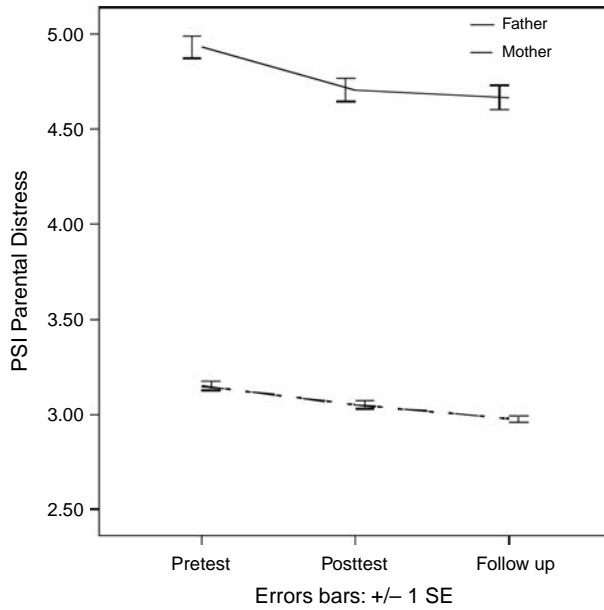

Figure 7. Comparison of mother and father levels of parental distress.

Figure 8. Comparison of teacher and parent ratings of protective factors for the *Fun FRIENDS* group.

Discussion

This study was the first to examine the effectiveness of a universal school-based delivery of the *Fun FRIENDS* programme with children aged 4–7 years. The findings provide promising support for early intervention models for reducing anxiety and increasing social and emotional strength in this population regardless pre-intervention anxiety

symptomatology. This has important implications for the prevention and treatment of anxiety in early childhood because it suggests that classroom-based universal early intervention programmes are sufficient to produce clinically significant change. The fact that intervention gains were maintained 12-month post-intervention provides further support and provides evidence for the importance of preventive universal intervention in early childhood. Given that formal education in early childhood has a clear focus on social–emotional development, prevention programmes that target emotional regulation and social competence have the potential to reinforce skill acquisition during the optimal developmental period (Humphries & Keenan, 2006).

A review of the main findings shows that compared with children in the waitlist condition, children in the two active conditions demonstrated greater symptom reduction and enhancement of social and emotional competence. Overall, both active intervention conditions appear to have produced significant and comparable gains; however, the *Fun FRIENDS* intervention produced greater improvements at post-intervention and follow-up. The results have clear implications for early intervention, providing support for the positive impact of the *Fun FRIENDS* programme in terms of enhancing social and emotional competence in this population. Delays or impairments in emotional regulation and social competence are associated with maladaptive coping behaviour and increased risk of childhood psycho-pathology including anxiety disorders (Southam-Gerow & Kendall, 2000).

Another finding of the study demonstrated significant decreases in BI from pre- to post-assessment and at the 12-month follow-up for the IG suggesting that changes in anxiety can positively impact BI. Research indicates the enhancement of a child's ability to regulate emotional reactivity may contribute to a resilience process and subsequently lead to decreases in BI, and potentially reducing symptoms of anxiety (Ballespi, Janeé, & Riba, 2012).

A significant finding of the study was that fathers rated levels of parental distress and negative perceptions of their child's behaviour a great deal higher overall than did mothers; however, both mothers and fathers showed significant improvements over time. This may occur through the process of enhancing parental confidence and fostering heightened awareness. Improved insight may translate into flexibility of maladaptive parenting attitudes and behaviours, such as over control and over protection. Further by teaching parents positive coping strategies to assist their children to regulate emotions, this may result in a decrease in frustration and greater understating of their child's anxiety. These results provide support for the inclusion of parents in interventions for young children with anxiety and have implications for behavioural difficulties because the study had a positive impact on behavioural issues post-intervention. Although this was not a specific objective of the intervention, this is an important finding given the negative impact on bullying and difficulties with peer relationships on development and psycho-social functioning.

A comparison of high versus low anxiety in the active group showed that despite differing baseline scores pre-assessment, both groups achieved a comparatively positive response post-intervention with continued improvement at 12-month follow-up. Further analysis on the high- versus low-anxiety groups demonstrated decreased BI for both groups, with only the high-anxious group maintaining improvements at 12-month follow-up. This finding may suggest that independent of risk status is possible to positively impact levels of BI and enhance positive coping behaviour for highly anxious children through a universal intervention. However, the dose requirements for children presenting with high BI may be greater than children with low levels at initial assessment.

In terms of protective factors, both parents and teachers reported improvements in children's emotional and behavioural competence over time for the IG, with parents reporting larger improvements. Although there was a difference in the extent of improvement between parents and teachers, this concordance is important because it suggests that the *Fun FRIENDS* intervention facilitated by teachers in the school setting has the potential to enhance positive coping and resilience across contexts (Figure 8).

Limitations

There were a number of limitations of this study. First, the lack of adherence and social validity data may have implications for the validity of some of the findings. It is recommended that future studies include both adherence and social validity assessment. Likewise, there may have been an issue with the continuity or delivery of the programme given the number of teachers involved. Second, the level of missing or incomplete data represents a significant limitation. It is likely that much of this missing data are related to the length of the questionnaires and that the schools allocated to the 12-month waitlist did not have any short-term incentive to participate. It is recommended that future researchers address this issue in the form of incentive or by offering assessment via telephone or Internet. Lastly there may have been some issue with consistency regarding the number of participating classes per school, which may have impacted on results.

Strengths

Strength of the study was the methodology used because of the inclusion of both a comparison, 12-month waitlist group and allows for more control of maturation and other factors that may impact results. Furthermore, the inclusion of asset-based and deficit measures is also of value, as the focus of the intervention is not simply to achieve reduction in symptoms but also promotion of optimal wellness and positive coping through skill acquisition.

The *Fun FRIENDS* programme is a manualized programme. The use of a facilitator's manual outlining the important components of the intervention, balanced with the opportunity for facilitators to be flexible and creative, whereas tailoring the intervention is an advantage and addresses the criticisms associated with other manualized programmes (see Addis, Cardemil, Duncan, & Miller, 2006; Addis & Krasnow, 2000). This approach to intervention is consistent with Kendall and Beidas's (2007) call for 'flexibility within fidelity' an umbrella term referring to the application of central components of intervention, while customizing to the child (Kendall et al., 2012).

A further strength of the study is the inclusion of both mother and father measures of anxiety and distress. This is of value due to the relative neglect of the father's role in early childhood anxiety with recent research showing a child's reactive temperament has an adverse effect on father's parenting in particular (Bögels & Phares, 2008; Majdandžić, de Vente, Feinberg, Aktar, & Bögels, 2011).

Future directions

Summary

The majority of school-based prevention programmes have focused on older children and adolescents. Given the high prevalence and early onset of anxiety disorders, there may be significant advantages in preventive intervention targeting young children in an attempt to avoid significant suffering and impairment. Findings from this trial of the *Fun FRIENDS*

intervention provide preliminary support for the effectiveness of universal implementation of the programme in schools, for children with varying levels of pre-intervention anxiety. Improvements in BI, social and emotional competence and reductions in behavioural difficulties were observed in addition to decreases in levels of parenting distress. The next step in evaluating the effectiveness of this programme will be to replicate the findings, conducting a randomized controlled trial with long-term follow-up and the inclusion of additional measures. There are a number of implications of this study, which are discussed.

It is recommended that future studies may benefit from designing psycho-educational sessions, either briefer or enhanced accessibility for parents via internet or phone to improve parental participation. This may have increased benefits for child and parental anxiety and may enhance maintenance of treatment gains. Furthermore, longer-term follow-up of more than 2 years is recommended in an attempt to detect real prevention effects as the literature suggests that follow-up of this length is required in order to ascertain prevention effects (Humphries & Keenan, 2012).

Given our limited understanding of the aetiological models for anxiety in preschoolers the inclusion of measures such as parenting behaviour and parent–child interactional processes is also recommended. Given the importance of the relationship between childhood anxiety and parental attitude, further research is required to assess whether changes in emotional regulation mediate changes in anxiety. This study demonstrates that a low-cost universal intervention is effective at reducing anxiety and at the same time addresses the multitude of barriers children and families face when accessing help.
